## ABSTRACT

The current COVID-19 pandemic has made patent the need for rapid and cost-effective diagnostic tests, crucial for future infectious outbreaks. qPCR is still considered the gold standard for pathogen detection, but relies on centralized, expensive equipment, leading to major difficulties for on-site detection. To overcome these limitations, loop-mediated isothermal amplification (LAMP), arises as a promising alternative. However, the development of simple, affordable, sensitive, and robust methodologies is still key for achieving quantitative point-of-care analysis.

In this work we have developed a sensitive, fast, and simple SARS-CoV-2 detection methodology combining reverse-transcription LAMP with electrochemical detection. This is based on the oxidation of phenol red (PR), a visual LAMP indicator that is also electroactive. Thus, we have developed a quantification method with a limit of detection of 21copies per reaction. This methodology has been applied to the analysis of nasopharyngeal swab samples, resulting in total concordance with clinical

1 RT-qPCR results. We have also designed and fabricated a small portable heater for LAMP purposes  
2 in extra-laboratory facilities, with a performance comparable to a commercial thermal cycler.

## INTRODUCTION

1  
2  
3  
4 The COVID-19 pandemic, caused by SARS-CoV-2, has highlighted the need for point-of-care (POC)  
5  
6 diagnostics, providing rapid, accurate and on-site results, so the infected individual can be quickly  
7  
8 isolated [1], with analytical devices delivered to end users. Although several vaccines have been  
9  
10 developed and successfully administered [2], the rise of new variants and the refusal or delay in  
11  
12 vaccination makes essential the development of decentralized, yet sensitive tests [3]. Aside from  
13  
14 COVID-19 pandemic, attention to other zoonotic outbreaks is required, with field-deployable  
15  
16 diagnostics technology ready.  
17  
18  
19  
20  
21

22 The gold-standard for SARS-CoV-2 testing is RT-qPCR (reverse-transcription quantitative  
23  
24 polymerase chain reaction) which relays on amplification and detection of the viral genome [4] with  
25  
26 exceptional sensitivity and specificity, but requiring pre-processing steps, expensive equipment, and  
27  
28 trained personnel. Other option is the use of POC tests, such as antigen or antibody assays [5] that  
29  
30 can be even performed by the end user but provide frequently lower sensitivity and high false negative  
31  
32 rate, especially in asymptomatic patients [6]. The optimal middle ground would be a diagnostic tool  
33  
34 providing sensitivity and specificity as close as possible to RT-qPCR, but also portable, fast, easy-to-  
35  
36 use and with affordable costs.  
37  
38  
39  
40  
41

42 An approachable alternative is RT-LAMP (reverse-transcription loop-mediated isothermal  
43  
44 amplification), performed at *ca.* 65 °C throughout the whole reaction process, with no need of  
45  
46 temperature cycles, and with shorter reaction time. It relies on the formation of loop-shaped secondary  
47  
48 structures along the amplification [7]. Furthermore, this technique presents a sensitivity comparable  
49  
50 to RT-qPCR in detecting COVID-19 in the acute phase of the illness, being an appropriate alternative  
51  
52 diagnostic tool [8].  
53  
54  
55  
56

57 Conventional LAMP reaction readouts rely on turbidimetric, colorimetric and fluorimetric approaches.  
58  
59 Observing changes by the naked eye is simple and useful for semiquantitative purposes. However,  
60  
61  
62  
63  
64  
65

1 quantitative analysis requires the implementation of instrumental methodologies, with additional  
2 workflow steps that difficult the decentralization. For this purpose, electrochemical techniques have  
3 provided sensitive methods yet robust and decentralizable. Several approaches have been  
4 implemented to detect and/or quantify LAMP products, all of them relying on intrinsic changes that  
5 occur in the reaction solution (e.g., DNA synthesis, pH drop or inorganic pyrophosphate release).  
6 Some direct strategies have been proposed, as those based on the change of conductivity and  
7 resistance [9] or pH, employing e.g., a hydrogen ion selective electrode containing a ionophore  
8 membrane [10] or a combined iridium oxide/carbon paste two-electrode system [11]. Alternatively,  
9 electrodes modified either with conductive polymers or metal nanoclusters which formal potential  
10 changes with pH [12] have been also employed. Indirect strategies are based on the use of  
11 electrochemical reporter molecules that can be either free in the reaction medium, such as Hoechst-  
12 33258 [13] or conjugated to DNA-probes as in the case of ferrocene-labelled strands [14].

20  
21  
22  
23  
24  
25  
26  
27  
28

29 Creative strategies are very interesting but the introduction of more reagents and steps increases  
30 costs and complicates the procedure. However, approaches based on a change in the  
31 electrochemical process of molecules are already present in commercial LAMP kits, usually as  
32 colorimetric indicators, do not suppose an important workflow change and can provide extra  
33 information. On the other hand, as the redox species is always at high concentration, a clear, precise,  
34 and well-defined analytical signal could be monitored. For this purpose, phenol red (PR) visual  
35 indicator is an excellent option since it is a widely used colorimetric probe for LAMP detection, coming  
36 already pre-mixed in many commercial kits. It presents a characteristic oxidation process that shifts  
37 to more positive potentials as pH drops, which can be very useful for electrochemical detection in  
38 slightly buffered media as is the case of LAMP reactions [15].

55 In this work we have developed a fast, sensitive, and precise SARS-CoV-2 electrochemical detection  
56 for RT-LAMP reactions (RT-LAMP-ED). This methodology, with diagnostic potential, can be easily  
57 performed with simple portable devices. For that purpose, we have developed a small lightweight  
58  
59  
60  
61

65

heater that can perform isothermal LAMP amplifications outside the laboratory or healthcare facilities.

This is the first time that PR is used not only as colorimetric but also as electrochemical indicator for the determination of SARS-CoV-2 in clinical nasopharyngeal samples.

## MATERIALS AND METHODS

**Sample collection.** Nasopharyngeal (NP) swab samples were collected at the Central University Hospital of Asturias (HUCA). Swabs were introduced in a microcentrifuge tube containing 500  $\mu\text{L}$  of 10 mM Tris-EDTA (TE) pH 8.0 buffer. Samples were inactivated at 95  $^{\circ}\text{C}$  for 5 min prior to its transportation [16] to our laboratory. The effect of proteinase K (Recombinant, PCR-Grade, ThermoFisher) treatment of samples was assessed at a final concentration of 0.04  $\text{mg}\cdot\text{mL}^{-1}$ . This study was carried out in accordance with the recommendations of the Ethical Committee on Regional Clinical Research of the Principality of Asturias.

**LAMP Assay.** Three sets of six specific LAMP primers were used based on sequences from previous studies [17–19] to amplify fragments N, N1 and S of SARS-CoV-2 genome. Primer sequences can be found in Table S1.

The reaction mix using WarmStart® Colorimetric LAMP 2X Master Mix (DNA & RNA) (New England Biolabs) contained 1x master mix (including *Bst* 2.0 DNA Polymerase and phenol red), 0.7 mM dUTG, primer mix (1.6  $\mu\text{M}$  each FIP and BIP primer, 0.2  $\mu\text{M}$  each F3 and B3 primer and 0.4  $\mu\text{M}$  each LoopF and LoopB primer), 0.3 U Antarctic Thermolabile UDG (Uracyl-DNA-Glycosylase) (New England Biolabs) and PCR-grade  $\text{dH}_2\text{O}$  (Invitrogen UltraPure™ Distilled Water (DNase/RNase free), Life Technologies) up to 24  $\mu\text{L}$  of final volume. 1  $\mu\text{L}$  of template SARS-CoV-2 RNA (VR-1986D, ATCC®), if required, was added at the desired concentration. All concentrations are indicated as copies· $\mu\text{L}^{-1}$  of standard or sample solution. 1  $\mu\text{L}$  of PCR-grade  $\text{dH}_2\text{O}$  was added to negative (non-template) control reactions. All reactions were performed on low-retention, nuclease-free PCR grade tubes (PCR-02-L-C, Axygen™) under sterile conditions in a laminar flow hood. To prevent carryover contaminations,

1 all the equipment was cleaned with 5% sodium-hypochlorite solution. Reactions were incubated in a  
2 thermal cycler (Veriti 96 Well Thermal Cycler, Applied Biosystems) at 65 °C for 30 min, with an initial  
3 step of 10 min at 37 °C for UDG activity. If using the portable heater (with constant 65 °C) this UDG  
4 step was carried out at room temperature prior to amplification. Samples were then kept at 4 °C for  
5 improved colour contrast.  
6  
7  
8  
9

10  
11  
12  
13 **Electrochemical detection.** Electrochemical measurements of the amplifications were performed  
14 using thick-film electrodes (S1PE, Micrux Technologies) connected to a  $\mu$ AUTOLAB TYPE III  
15 potentiostat (Metrohm), which was controlled by NOVA Software 2.1.5, through a box connector (ED-  
16 SPE-BOX, Micrux Technologies). The screen-printed electrodes (SPEs, dimensions 27.5x10.1x0.35  
17 mm) consist of three electrodes: a circle-shaped working electrode with a 3-mm diameter and a  
18 counter electrode, both made of carbon ink, and a reference electrode made of silver ink. To perform  
19 the electrochemical measurements, 25  $\mu$ L were deposited covering the three electrodes. The  
20 measurements were recorded at room temperature and one three-electrode card was used for each  
21 measurement. Cyclic voltammograms (CVs) were recorded scanning the potential from +0.2 to +0.9  
22 V at a scan rate of 0.1 V·s<sup>-1</sup>.

33  
34  
35  
36  
37

38 **Image Analysis.** Images from the calibration curve were analysed using the open-source image  
39 processing software ImageJ [20]. Green (from RGB) and hue (from HSV) channel intensity values  
40 were measured for quantification. For green channel analysis, images were RGB split and then  
41 measured in the green channel, as it has been previously reported [21]. For hue analysis, hue was  
42 rotated 140° using the HueRotation plugin. Then a HSB split was performed, and a subsequent hue  
43 quantification was carried out [22].

53 **Statistics.** Results in this study are represented as mean value  $\pm$  standard deviation (SD). Differences  
54 between data groups were analysed using Student's T-test (two-tailed, non-paired samples). Samples  
55 were previously tested for normality and homogeneity of variance using the Shapiro-Wilk and

3 and  $p < 0.005$  (\*\*\*)  
4  
5

## 6 **Small portable heater for LAMP amplifications**

7  
8  
9

10 The small and portable heater for LAMP purposes is comprised of a heater cavity with room for a set  
11 of samples (approximately 6 to 8 PCR tubes) and a 3D printed PLA case and lid. This cavity is heated  
12 by an internal heating surface, which is electronically controlled by a PWM (pulse width modulation)  
13 signal to keep the temperature fine-tuned during the amplification process.  
14  
15  
16  
17  
18  
19  
20  
21

22 The heating system is composed by a resistive film (DuPont™ Kapton® RS) powered by a boost  
23 converter, which converts the voltage of a battery or wall adapter to the voltage required by the heater.  
24 To control and tune the voltage value provided by the converter, a PWM signal switches the power  
25 supplied to the heating film. The temperature is measured by a thermocouple sensor located in the  
26 heating surface. The acquired temperature signal is dispatched to the microcontroller, which, by  
27 comparison with the target temperature value and a PID control loop, establishes the pulse width of  
28 the PWM signal. This signal sets the voltage switching process. To achieve the portability feature, the  
29 power can be supplied from a wall adapter, but also from a portable power bank. The heating  
30 temperature and working time re programmable. The device presents a LED light indicating whether  
31 it is heating up (green light) or has already reached a stable temperature (blue light). The temperature  
32 of the heater was assessed using a digital thermometer with a temperature probe (UT320, UNI-T).

## 48 **RESULTS**

49  
50  
51  
52

### 53 **Electrochemical detection of the N gene amplification**

54  
55  
56  
57

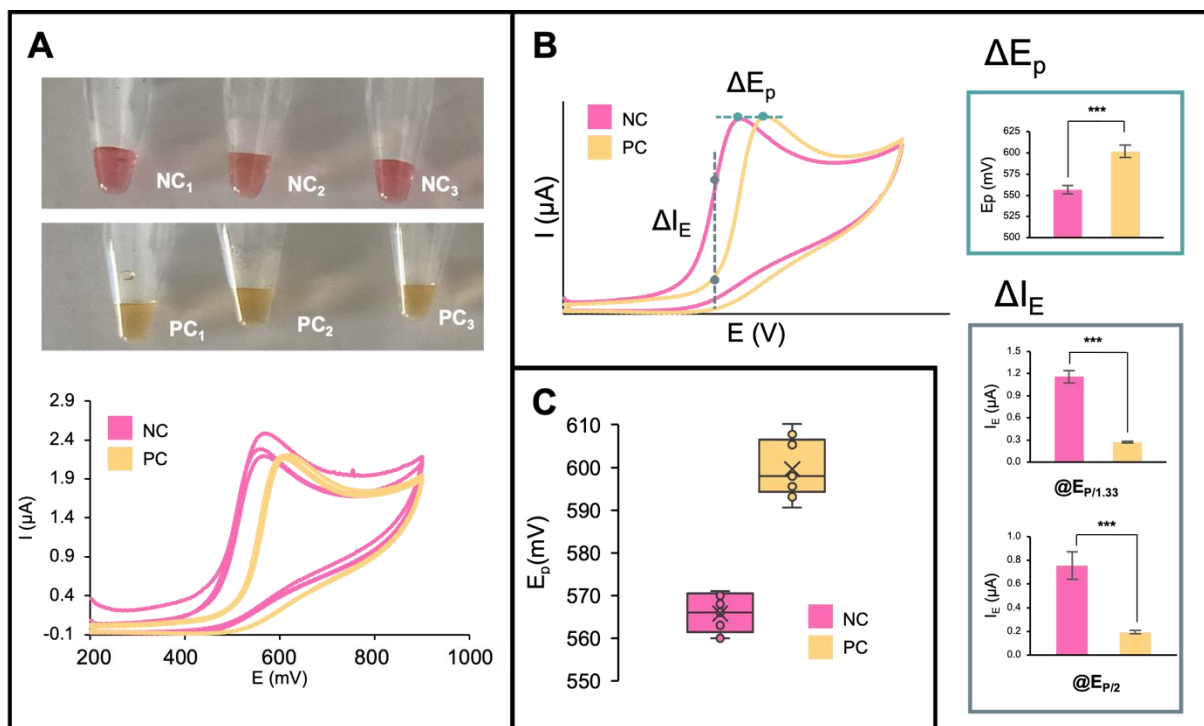

58 A fragment of the nucleocapsid gene (N gene) of the SARS-CoV-2 sequence was first amplified to  
59 assess the possibility of performing a quantitative electrochemical detection. For this purpose, RT-  
60  
61  
62  
63  
64  
65

1 LAMP reactions of the N fragment were performed. The results of this assay can be observed in  
2 Figure 1A (top). Three negative (non-template) controls (NC) were assessed, as well as three positive  
3 controls (PC, 2148 RNA copies· $\mu\text{L}^{-1}$ ). A colour shift from pink to yellow can be observed when the  
4 RT-LAMP reaction has occurred. For the electrochemical detection, the CV results obtained show the  
5 anodic process of PR, with a clear shift towards more positive potentials from negative to positive  
6 controls (Figure 1A, bottom). The precision of the peak potential ( $E_p$ ) is excellent:  $557 \pm 5$  mV for  
7 negative and  $602 \pm 7$  mV for positive controls. This suggests that the difference in  $E_p$  could be an  
8 adequate analytical signal. However, the difference in the peak current intensity ( $I_p$ ) is not significant,  
9 with a value of  $1.52 \pm 0.03$   $\mu\text{A}$  for negative controls and  $1.48 \pm 0.02$   $\mu\text{A}$  for positive controls.  
10

13  
14  
15  
16  
17  
18  
19  
20  
21

22 Based on these results, different readout possibilities for the electrochemical measurements can be  
23 established (Figure 1B). The main response parameters to be considered in a CV are  $E_p$  and  $I_p$ . The  
24 first is relevant for qualitative analysis, since each species is oxidized/reduced at a specific potential  
25 for a given electrochemical system, phenol red/LAMP medium/SPE in this case. However, as the pH  
26 medium changes and protons are involved in the PR redox reaction, a movement in its  $E_p$  is produced.  
27 Therefore, this parameter (or its shift,  $\Delta E_p$ ) can be employed with quantitative purposes, as is  
28 proportional to the concentration of protons. In the LAMP reaction, protons are released when  
29 nucleotides are added to the strand and then, a decrease in pH is produced. Since PR moves towards  
30 more positive potentials with decreasing pH, this potential shift can be correlated with the number of  
31 initial RNA copies and calibrated for different concentrations of viral RNA. On the other hand,  $I_p$  can  
32 be used for quantitative purposes since it is proportional to the concentration of the electroactive  
33 species. In this case, there is not a significant change ( $\Delta I_p$ ) for PR. However, in the CV curves of  
34 Figure 1B, a difference in the current intensity measured at a fixed potential corresponding to the  
35 peak potential of the negative control or lower ( $E_p$ ,  $E_{p/1.33}$ ,  $E_{p/2}$ ...), can also be measured ( $\Delta I_E$ ). As  
36 positive reactions experiment a shift towards higher potential values, they will have lower intensity  
37 current at the given potential when compared with negative controls. Then, it could be also calibrated  
38 for different concentrations of viral RNA.

**Figure 1.** Electrochemical detection of the LAMP amplification of the N fragment of SARS-CoV-2. A: Visual (top) and electrochemical (bottom) result of the amplification. B: Different electrochemical readout possibilities. Analytical signals obtained. \*\*\*:  $p < 0.005$ . Error bars represent the SD for three different amplifications. C: Box-and-whiskers plot for 10 negative reactions (pink) and 10 positive reactions (yellow). NC: negative control; PC: positive control (2148 RNA copies  $\cdot \mu\text{L}^{-1}$ ).

Figure 1B shows the two possible analytical signals obtained from CVs recorded after RT-LAMP reactions. Regarding  $\Delta E_p$ , we can observe a significant increase for positive samples. When considering  $\Delta I_E$ , we can observe a significant decrease at a potential where the peak intensity is either 75% or 50% (half-peak potential) of the NC peak current intensity ( $@E_{p/1.33}$  and  $@E_{p/2}$ , respectively). This gives two valuable interpretations of the CVs to choose the best analytical signal.

The robustness of this method was evaluated measuring 20 amplifications (10 NCs and 10 PCs, with 2148 copies  $\cdot \mu\text{L}^{-1}$ ) of the same fragment using 20 different SPEs (Figure S1). Figure 1C shows the box-and-whiskers plot obtained representing  $\Delta E_p$  for both groups. The relative standard deviation was 1.2% for positive and 0.8% for negative amplifications, indicating a high precision of the LAMP-ED

1 methodology. The fact that PR is present at high concentration and shows a clearly defined signal is  
2 probably the main reason.  
3  
4  
5

### 6 **Calibration curve for SARS-CoV-2 quantification using RT-LAMP-ED**

7  
8  
9

10 Besides N fragment, other target sequences were evaluated to optimize the detection methodology.  
11 Two additional different fragments were amplified, comprising a sequence belonging to the S (spike  
12 protein) gene and the N1 fragment of the nucleocapsid gene (amplification results and fragment  
13 locations within SARs-CoV-2 genome can be seen in Figure S2). Starting from 3 different initial  
14 concentrations of RNA, the  $\Delta E_p$  after LAMP amplification was measured. As it can be observed in  
15 Figure S3, 107 and 214 copies· $\mu\text{L}^{-1}$  can be clearly differentiated from NC only in the case of the N1  
16 fragment. A linear relationship can also be observed when amplifying this region with a change of *ca.*  
17 16 mV per order of magnitude of RNA concentration. In the case of S and N sequences, the values  
18 for 107 and 214 copies were below the dashed lines, that correspond to 3 times the SD of the NC  
19 signal. Therefore, the fragment N1 was considered for further studies.  
20  
21

30  
31  
32  
33  
34

35 To develop a quantitative detection method, a calibration curve with different initial concentrations of  
36 RNA was performed, amplifying the N1 region (Figure 2A). RT-LAMP reactions were performed  
37 thrice, and an initial visual (naked eye) assessment was performed (Table at Figure 2A). Although  
38 amplifications starting from 107 copies· $\mu\text{L}^{-1}$  can be clearly distinguished as positive, it is difficult to  
39 discern those with lower copy number.  
40  
41  
42  
43  
44  
45  
46  
47  
48

49 Calibration curves based on electrochemical measurements (Figures 2C and 2D) were obtained  
50 measuring both  $\Delta E_p$  and  $\Delta I_E$  at a potential corresponding to a 75% and 50% intensity of that of the  
51 peak potential for NCs ( $E_{p/1.33}$  and  $E_{p/2}$ , i.e., 556 and 534 mV respectively). The  $\Delta E_p$  (compared with  
52 NCs) shows a good linearity with the starting RNA concentration over almost three orders of  
53 magnitude. Figure 2D presents values of  $\Delta I@E_{p/1.33}$  when compared to NCs, while Figure S4 shows  
54 the values of  $\Delta I@E_{p/2}$ , with a lower coefficient of determination. Then,  $\Delta E_p$  was chosen for further

1 studies, as it shows good linear fit and sensitivity and it simplifies data analysis. The potential shifts  
2 16.2 mV per order of magnitude, which agrees with this commented for Figure S3, indicating the  
3 robustness of the LAMP-ED methodology.  
4  
5  
6  
7

8 Reactions were also analysed using ImageJ. Pictures after amplification were captured and analysed  
9 using ImageJ following two procedures reported in the bibliography [21,22] for PR based LAMP  
10 amplifications. The comparison of both analyses (Figure S5) shows that hue values, albeit showing  
11 lower increases, follow a linear tendence. Green values appear to be very sensitive to irregular  
12 brightness, as this method was first proposed for paper-based amplification, where image artifacts  
13 were not as relevant. On the other hand, the method proposed by Scott et al. relies on tube-based  
14 amplifications, where uneven brightness can be a common artifact, and thus this method is more  
15 suitable for our analysis. Green channel intensity is an easier parameter to obtain in terms of image  
16 processing, and brightness and reflections can be avoided using specialized image acquisition  
17 equipment [23]. The curve using hue values is shown in Figure 2A (right).

31  
32 An amplification starting from 5 copies per reaction was also performed (grey dataset in Figures 2B,  
33 2C, 2D and S4) but was not considered in the equation of the calibration curve as it was under our  
34 threshold value (3 times the standard deviation of the NC value) or showed a high variance. In any  
35 case, it fitted the linear trend of the  $\Delta E_p$  calibration curve ( $R^2 = 0.992$ ) as well as the current decrease  
36 curve ( $R^2 = 0.991$ ). The increase in variance of LAMP results when starting from low copy number  
37 (from 1 to 100 copies per reaction) has been previously reported compared to qPCR [4]. If dealing  
38 with low copy number samples, multiple amplifications should be thus performed to prevent false  
39 negative results. The RT-LAMP-ED method would then provide a qualitative (positive/negative)  
40 response, but if quantification is desired, a dilution of the sample should be done.

56 The limit of detection (LOD) calculated as 3 times the SD of the negative control divided by the slope  
57 of the linear fit is 1 copy- $\mu\text{L}^{-1}$ . However, we have established a more practical LOD considering a cut-  
58 off signal value of 11.5 mV, based on the lowest discernible concentration (21 copies- $\mu\text{L}^{-1}$ ). Any  
59  
60  
61  
62  
63  
64  
65

electrochemical measurement with a value below this would be considered a negative amplification. Based on the same approach, considering the higher concentration of the linear dynamic range (1428 copies· $\mu\text{L}^{-1}$ ) any electrochemical measure over 42.4 mV would be positive with a concentration of RNA over 1428 copies· $\mu\text{L}^{-1}$ . Samples with an electrochemical signal between 11.5 and 42.4 mV could be precisely quantified.

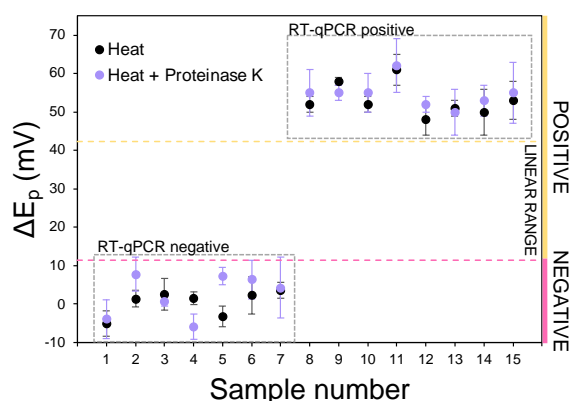

**Figure 2.** Calibration plots for the N1 fragment. A: (Left top) RT-LAMP amplification reactions, starting from different RNA template copies (copies· $\mu\text{L}^{-1}$ ), (left bottom): Visual assessment of the amplification and (right) image analysis calibration curve using hue values. B: CVs recorded for end-point amplifications of different RNA copies· $\mu\text{L}^{-1}$ . C: Anodic peak potential shift calibration curve. D: Intensity of current shift calibration curve at a potential of 75% the intensity at the NC peak potential. Grey dataset corresponds to the values measured but not included in the curve. Error bars represent the SD for three different amplifications. In all cases, the dashed red line corresponds to three times the SD of the non-template controls.

## Sample assessment

To validate the procedure, 15 nasopharyngeal (NP) swabs of volunteering individuals taken at the HUCA were analysed. Firstly, the suitability of the medium employed for further qPCR analysis, i.e., viral transport medium (VTM), was evaluated electrochemically recording a CV under the same conditions than those for RT-LAMP-ED. This medium presented an oxidation process starting at around +0.55 mV, with current intensities up to 400  $\mu\text{A}$  (data not shown), overlapping the process of PR. To overcome this, TE buffer was used as sample collection medium. Two samples were taken per individual, for RT-qPCR and RT-LAMP-ED. All samples were heat inactivated prior to analysis. This procedure has proven to be sufficient for both safety handling of SARS-CoV-2 samples [16] and extraction-free amplification [24].

Results of the here proposed method were compared with their corresponding RT-qPCR result (Figure 3). Due to the high viral load of the patients, all the positive sample electrochemical measurements were above the upper limit of the linear range and thus classified as positive. Most COVID-19 positive patients have a nasal swab viral load spanning from  $10^3$  to  $10^{11}$  copies· $\mu\text{L}^{-1}$  of sample [25]. Then, our low-LOD methodology, results very adequate to avoid false negative results. Apart from the thermal deactivation, the use of proteinase K for improvement of the extraction-free amplification procedure was also assessed. Results for the analysis are shown in Figure 4 (purple dataset), with this pre-treatment not showing any significant difference.

**Figure 3.** Clinical sample analysis. Each sample was analysed using RT-qPCR (grey boxes) and RT-LAMP-ED. For RT-LAMP-ED results, heat inactivated samples with Proteinase K (purple dataset) or without Proteinase K (black dataset) are represented in terms of shift in peak potential. Pink dashed line represents negative cut-off value, yellow dashed line represents positive non-quantifiable cut-off value. Linear range (in between) is also indicated. Error bars represent the SD for three different amplifications.

Even with a rather small sample (n=15), our RT-LAMP-ED methodology showed 100% sensitivity and specificity when compared to routine RT-qPCR performed on the corresponding laboratories. A bigger cohort study would be necessary for determining these analytical parameters with higher significance. On the other hand, although classification into positive and negative samples is the most important with special care in avoiding false negatives, quantification of highly positive samples can be of interest to monitor the infection. Therefore, a series of dilutions (1:5, 1:50 and 1:100) were prepared and assayed for quantitative purposes in three samples (Table 1).

**Table 1.** Clinical sample dilution analysis. For each sample, the dilution copy number was determined using the calibration curve.

Sample	Dilution	RT-LAMP-ED [RNA] (copies· $\mu\text{L}^{-1}$ )
10	1:5	420 $\pm$ 71
	1:50	33 $\pm$ 8
	1:100	17 $\pm$ 1
11	1:5	470 $\pm$ 30
	1:50	51 $\pm$ 9
	1:100	21 $\pm$ 1
12	1:5	350 $\pm$ 5
	1:50	33 $\pm$ 13
	1:100	12 $\pm$ 3

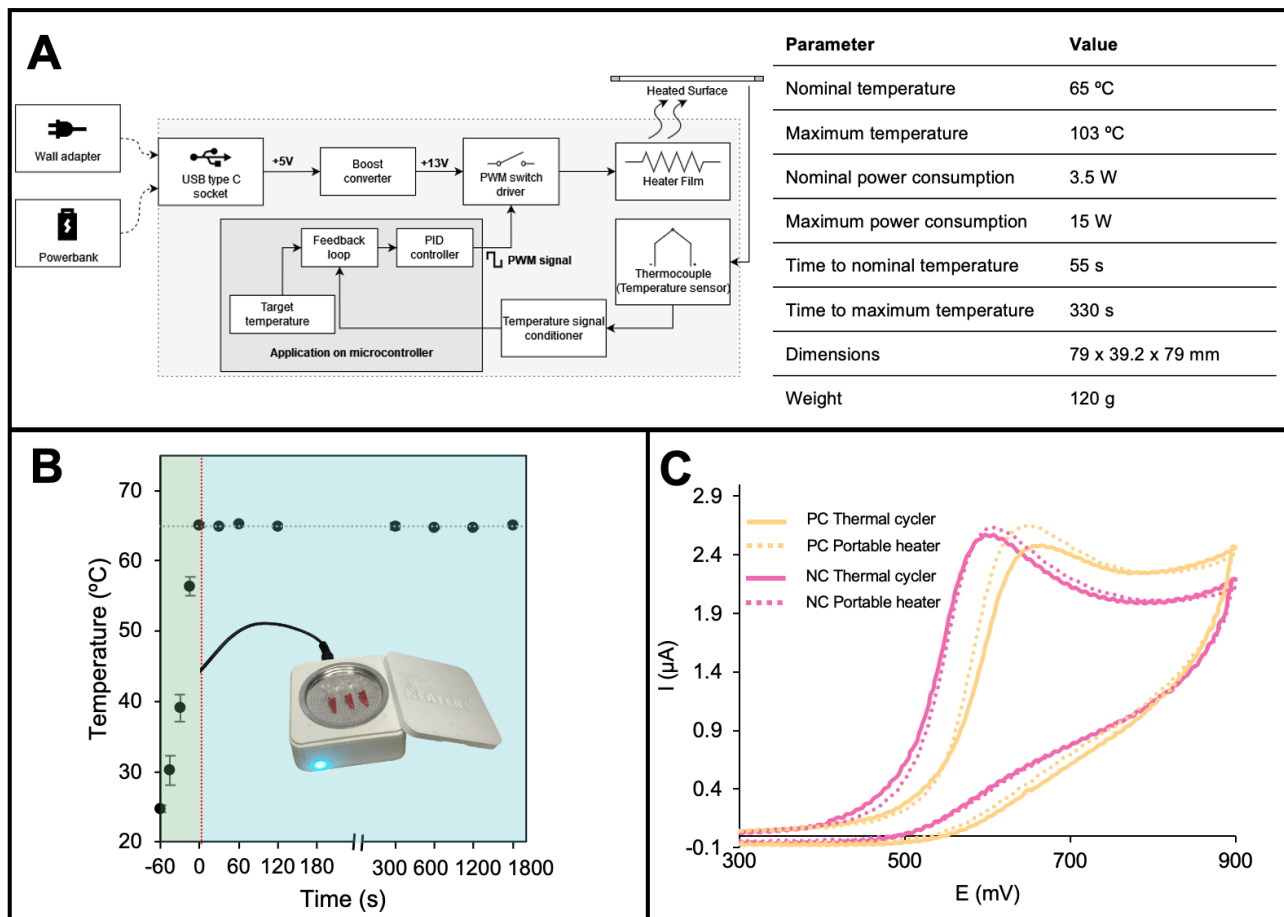

1  
2 In all the cases, a 1:5 dilution was enough to include the analytical signal within the linear dynamic  
3 range. Therefore, quantification was possible with this dilution. Further dilutions were performed to  
4 prove the linearity of the response (Figure S6). The 1:100 dilution led to values below the linear range,  
5 and thus dilutions over this ratio should not be performed.

### 10 **Towards (RT)-LAMP-ED decentralization: portable heater**

11  
12 To decentralize the reaction workflow, a novel heating device has been designed and implemented  
13 (Figure 4A). The main features are its small size and weight, portability, and user-friendly interface.  
14  
15 The specifications are shown also in Figure 4A. This device has also been characterized in terms of  
16 its temperature. Figure 4B shows the values obtained for three study replicates, allowing the device  
17 to cool between studies. This portable heater showed a great performance, achieving the setpoint (65  
18 °C) in less than 1 min and keeping the temperature stable for at least 30 min.

28  
29  
30

31 For assessing the adequate performance of the RT-LAMP portable heater, amplifications were  
32 parallelly carried out under the same conditions on said heater and a commercial thermocycler. In  
33 both cases 3 negative and 3 positive (2148 copies of RNA· $\mu\text{L}^{-1}$ ) reactions were performed and CVs  
34 were recorded. Figure 4C shows the comparison, where the concordance in voltammetric outcomes  
35 can be seen. No significant differences in the analytical signal were observed between methods.  
36  
37 proving the usefulness of this heater for on-site applications or for settings where a thermal cyclers  
38 might not be available.

Error bars represent the SD for three different measurements. A photograph of the heater with three PCR tubes for size comparison is included as an inset. C: CVs for a batch of reactions performed on a thermal cycler and the portable heater. One CV for each batch is shown in the image. NC: Negative control; PC: Positive control.

## CONCLUSIONS

In this work, we have established a simple, fast, and sensitive method for the electrochemical determination of SARS-CoV-2 using RT-LAMP. We have assessed three different target regions, with the N1 region showing the best performance. The analytical signal was based on changes occurring on phenol red, visual LAMP indicator already included in the master mix. During the LAMP reaction the pH changes and thus the colour and the redox process of phenol red. Five different parameters

1 were analysed, optical ( $\Delta\text{Green}$  and  $\Delta\text{Hue}$ ) and electrochemical ( $\Delta E_p$ ,  $\Delta I@E_{p/1.33}$  and  $\Delta I@E_{p/2}$ ). The  
2 parameter that best fitted our purpose of decentralization was  $\Delta E_p$ , which also presented the best  
3 linear fit. This is the first time SARS-CoV-2 is detected using this methodology. Clinical samples were  
4 analysed and compared to routine RT-qPCR results, showing 100% of sensitivity and specificity. The  
5 low LOD (theoretical: 1 copy· $\mu\text{L}^{-1}$ ; practical: 21 copies· $\mu\text{L}^{-1}$ ) makes this methodology very adequate  
6 for classification of dubious samples in a simple manner. The methodology can be easily adapted to  
7 the detection of new pathogenic threats once the sequence is known.

17

18 For decentralization purposes, a portable heater was designed, fabricated, and characterized. Its  
19 performance was evaluated against a benchtop thermal cycler, with comparable results. Work is in  
20 progress to integrate heater and potentiostat in a small device for combining amplification and  
21 detection, to advance towards pocket diagnosis.
